

Quetiapine-Induced Hypersalivation

Sir: Quetiapine fumarate is a dibenzothiazepine-derivative antipsychotic with combined antagonism at dopamine (D_1 , D_2) and serotonin type 1 and type 2 (5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C}) receptors. Additionally, quetiapine antagonizes α_1 - and α_2 -adrenergic and histamine H₁ receptors. Protean binding at the above receptors explains the common side effects, which include hypersomnolence, hypotension, headache, weight gain, and gastrointestinal disturbance. However, to our knowledge, there have been no case reports of quetiapine-induced hypersalivation. We report the case of a patient with schizoaffective disorder taking low-dose quetiapine who developed hypersalivation, which remitted after discontinuation of the drug. We suggest that quetiapine antagonism at the α_2 receptor contributes to the phenomenon of hypersalivation.

Case report. Ms. A, a 36-year-old woman of Korean descent with a 16-year history of schizoaffective disorder, was admitted to the adult psychiatric medical care unit with a relapse of mania with psychosis. The patient's symptoms included elated mood, grandiose delusions of being a Power Ranger, disorganized behavior, and decreased need for sleep. The patient had been previously stabilized on clozapine with the only noted side effect being increased sedation. During this hospitalization, the patient refused administration of clozapine and instead was started on risperidone. Within a few days of commencement, the patient developed extrapyramidal symptoms with rigidity, dystonia, and slurring of speech, which prompted discontinuation of the risperidone. After a drug-free period of 3 days, the patient was started on quetiapine 25 mg b.i.d., and within a day, she developed increased salivation. When the dosage was increased to 50 mg b.i.d., the salivation worsened; the patient was drooling most of the day, and all of her clothing was wet. Benzotropine (1 mg p.o. b.i.d.) and atropine eye drops (0.1%) sublingually did not reduce the hypersalivation. The quetiapine was stopped, and 1 day later, the hypersalivation resolved.

Based on the temporal relationship between the administration and discontinuation of quetiapine and the onset and cessation of the patient's hypersalivation, it is possible that the hypersalivation was induced by the quetiapine. Hypersalivation is a common and distressing side effect seen with many psychotropic medications. However, no previous reports have associated increased salivation with the use of quetiapine. We attempt to explain the mechanism behind this event using the drug's known receptor affinities and the resultant binding effects observed in a closely related antipsychotic agent.

Among the antipsychotics, clozapine is well recognized for inducing increased, voluminous salivation early in the course of treatment in up to 54% of patients.¹ Clozapine is structurally similar to quetiapine and possesses a comparably broad receptor profile, which includes antagonistic activity at dopamine (D_1 , D_2 , D_3 , D_4) receptors, adrenergic blockade activity at the α_1 and α_2 receptors, and antagonism at serotonin 5-HT₂ receptors and histamine H₁ receptors. However, unlike quetiapine, clozapine possesses both agonistic and antagonistic properties at muscarinic receptors. Specifically, clozapine has antagonist activity at M₁, M₂, M₃, and M₅ receptors, but exhibits agonist

effects on the M₄ receptor. One proposed mechanism for clozapine-induced hypersalivation focuses on its antagonism of α_2 -adrenergic receptors.² Through blockade of sympathetic stimulation, parasympathetic stimulation is left unopposed to cause high salivary flow rates. Direct parasympathetic stimulation through its agonist effects at the M₄ receptor has also been suggested to explain clozapine-induced hypersalivation.³

Quetiapine and clozapine both share blocking affinity at α_2 -adrenergic receptors, whereas only clozapine has agonist properties at the M₄ receptor. We thus propose that α_2 -adrenergic blockade is the mechanism for quetiapine-induced hypersalivation. Further study is needed to draw definite conclusions regarding this proposed relationship.

Sleep-Related Hypomanic Symptoms as a Predictor of Bipolar Spectrum Disorders

Sir: Deciding whether to prescribe antidepressants for the depressed patients with bipolar spectrum disorders remains a challenge for clinicians. Two most-feared potential consequences of using antidepressants in patients with bipolar spectrum disorders are triggering a manic switch and/or generating a rapid cycling course of the disease.¹ Experts have long tried to recognize the depressed patients who are at a greater risk for switching to mania; thus, several symptoms have been suggested as "soft signs" of bipolarity, including hypersomnia, psychomotor retardation, young age at onset of depression, family history of bipolar disorder, drug-induced hypomania, seasonality of the episodes, and diurnal variation of the symptoms.² However, the list is not yet complete, and many cases still cannot be correctly predicted. As a result, clinical findings that could be used as new predictors of bipolar spectrum disorders could be helpful for future interventions.

Case report. Ms. A was a 27-year-old married woman who experienced an aggravation of depressive and anxiety symptoms for 6 months beginning in August 2005. Symptoms included depressed mood, loss of interest, repeated crying spells, loss of concentration, insomnia, decreased appetite, irritability, worry, and preoccupation with death.

Past history revealed no significant finding other than mild depressive and anxiety symptoms in the previous 4 years and no episodes of mania or hypomania.

She had no suggestive symptoms for a bipolar spectrum disorder except for very brief periods (about 30 seconds) of euphoria and inflated self-esteem, which occurred just before falling asleep, in a semiconscious state between wakefulness and sleep. During these periods, she experienced an exuberant sense of power, and she believed that she was able to "move mountains." Family history for bipolar disorder was negative.

The patient met the criteria for major depressive disorder based on DSM-IV-TR and received 5 mg/day of citalopram (February 2006), and after 5 days, the dose was increased to 10 mg/day, in addition to 1.25 mg/day of alprazolam, in 3 divided doses. One week later, the patient showed significant improvement. In addition, alprazolam had reduced the sleep latency, and the patient did not experience or remember any sleep-related hypomanic symptoms. Instead, she reported having distinct periods of euphoria and talkativeness 15 to 20 minutes after taking each dose of alprazolam. These periods would happen after all doses of alprazolam and would completely resolve after about 10 minutes, and the patient would return to her depressed baseline. The patient did not experience any other side effects other than a mild sedation during the day. The alprazolam dose was reduced to 0.75 mg/day to decrease sedation and then tapered to complete cessation in the next 3 weeks, and citalopram was continued. Sleep-related hypomanic symptoms did not recur after reducing or discontinuing alprazolam. The patient was followed for 6 more months and remained euthymic (August 2006).

Recent studies suggest that the lifetime prevalence of bipolar spectrum disorders in the general population is more than 6%,³ that is, much higher than what was previously speculated.² It is also reported that about 12.5% of the patients initially diagnosed as having depression will be reclassified as having a bipolar spectrum disorder in their course of illness.⁴

This patient reported experiencing distinct brief periods of euphoria and inflated self-esteem before sleep onset, which could potentially be related to bipolar spectrum disorders. Even though we did not have enough evidence to accept it as a new soft sign of bipolar spectrum disorders before starting the medications, transient hypomanic symptoms induced by taking alprazolam suggested that "sleep-related periods of euphoria" could be assumed as one of the predictors of bipolar spectrum disorders.

We are aware that had the patient been followed without decreasing the dose of alprazolam, she might not have developed a bipolar disorder. Obviously, this could not be performed because of ethical considerations. Future studies could tell more about the diagnostic value and effect of each of the soft signs on the long-term course of the disease.

A Case of Obsessive-Compulsive Disorder Responding to Duloxetine

Sir: Despite extensive clinical use of serotonin reuptake inhibitors, clomipramine, and venlafaxine¹ in the treatment of obsessive-compulsive disorder (OCD), to our knowledge there have been no reports on the use of duloxetine to treat patients with this disorder. We report the successful use of duloxetine to treat a patient with OCD.

Case report. Mr. A, a 38-year-old man, had an 8-year history of OCD (DSM-IV criteria), which began abruptly several months before his wedding and was characterized by senseless and recurrent thoughts that caused marked distress, such as, "Why do doors open and close?" and "Why does water fall out when a bucket turns upside down?" He felt compelled to repeatedly hit a door with his hands to relieve his distress; relief was only transient despite hitting the door all day long. The symptoms led to impaired work and social functioning. Treatment was begun in 1998 with clomipramine, 75 mg/day, and clonazepam, 3 mg/day, in addition to supportive psychotherapy. After 1 month of treatment, Mr. A had experienced significant symptomatic relief, though he had also developed loss of libido, retarded ejaculation, and anorgasmia. Clomipramine and clonazepam were discontinued, and he began treatment with paroxetine (60 mg/day), which he did not tolerate due to severe headaches, retarded ejaculation, and anorgasmia. Mirtazapine, 30 mg/day, was started to alleviate his sexual complaints.

For the next 4 years, his mild obsessional thoughts did not interfere with his daily activities. Without warning, Mr. A experienced the onset of sexual obsessions in 2003 that were extremely distressing and offended his moral sense. They were characterized by a recurrent impulse to stare at attractive women. This impulse was associated with an urgent need to change his facial expression (involving smiling, grimaces, or other facial contortions), which led to considerable anxiety. These symptoms led to social withdrawal and affected his normal routines. His antidepressant treatment was switched from mirtazapine to escitalopram (20 mg/day). He experienced mild improvement, which allowed him to return to his routine activities.

During the next 12 months, he was again bothered with persistence and worsening of his symptoms, experiencing 20 to 30 "crises" a day. With his consent, escitalopram treatment was discontinued and treatment with duloxetine (60 mg/day) was initiated. After 4 weeks and no symptom improvement, the dose was boosted to 120 mg/day. One month later, Mr. A had achieved remarkable symptom improvement, reporting no subsequent obsessional "crises." During a 1-year follow-up with duloxetine maintenance, he continued to do well. According to Mr. A, this is the longest period he had ever had free of intrusive obsessional thoughts. No side effects were reported.

Reports have implicated noradrenergic as well as the serotonergic neurotransmitter systems in the genesis of OCD.² For that reason, duloxetine, with its balanced serotonin-norepinephrine reuptake inhibition properties, may be worthwhile to study in the treatment of OCD.

Absence of Cardiac Side Effects During Treatment of Schizophrenia With Risperidone in a Patient With Wolff-Parkinson-White Syndrome

Sir: Excessive prolongation of the QT interval can predispose to a peculiar ventricular arrhythmia called *torsade de pointes*, or sudden cardiac death. QT prolongation has been found to occur with some older conventional and newer atypical antipsychotics.¹ Nevertheless, the recent literature suggests that atypical antipsychotics are not associated with torsade de pointes except in the case of a concomitant risk factor (e.g., polypharmacy, overdose, restraint, substance misuse, electrolyte imbalance).^{1,2}

The risk for QT prolongation does not seem to be the same for all atypical antipsychotics. Olanzapine seems to present a quasi-inexistent risk¹; risperidone, quetiapine, aripiprazole, and clozapine present weak to moderate risks²; and ziprasidone presents higher risks.¹ Sertindole has been associated with QT prolongation leading to fatal cardiac arrhythmias.

Other cardiovascular risks associated with antipsychotic use include cardiac factors such as long QT syndromes, ischemic heart disease, myocarditis, and sinus bradycardia.³ A case report of olanzapine-induced corrected QT (QTc) prolongation in a patient with Wolff-Parkinson-White (WPW) syndrome has recently been published.⁴

We report the clinical case of a 35-year-old man with DSM-IV schizophrenia and WPW syndrome who received treatment with risperidone.

Case report. In May 2004, Mr. A was hospitalized due to the exacerbation of paranoid delusions and auditory hallucinations. Because of compliance issues, we decided to administer long-

acting injectable risperidone, 50 mg, allied with an oral treatment of risperidone, 2 mg/day, during the first month. Concomitant treatment consisted of trazodone, 100 mg/day, and lorazepam, 15 mg/day. Before the start of treatment, the QTc interval was 420 ms. One week later, it was at 452 ms and 2 weeks later, 469 ms. A second injection of risperidone, 50 mg, was then administered. Subsequently, the patient refused further injections. Oral treatment with risperidone, 6 mg/day, was then administered. One month later, his psychotic symptoms improved, and his QTc interval was 472 ms.

Life-threatening ventricular arrhythmias in WPW syndrome are related to a rapid anterograde conduction throughout the bypass tract and are not related to torsade de pointes. Mr. A exhibited paroxysmal palpitations, and the baseline electrocardiogram showed intermittent pre-excitation from a left lateral accessory bypass tract. Pre-excitation regressed during sinus tachycardia with an enhanced conduction in the normal conduction system, suggesting a long refractory period within the bypass tract and a low risk for life-threatening ventricular arrhythmias.

In conclusion, WPW syndrome per se seems not to be a contraindication for atypical antipsychotics, and standard safety measures such as the regular measurement of the QTc interval and the avoidance of concomitant QT-prolonging drugs should be sufficient precautions when treating WPW patients with atypical antipsychotics.

The authors report no financial or other relationship relevant to the subject of this letter.

A Case of Late-Onset Pedophilia and Response to Sertraline

Sir: Pedophilia is a psychiatric disorder in a person at least 16 year old that is characterized by sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child (aged 13 years or younger).¹ These fantasies are acted out and cause marked distress or interpersonal difficulties. Pedophilia is a common and often overlooked syndrome that

risks the child victim's well-being and further psychosocial development and adaptive functioning. While a majority of cases of pedophilia begin among adolescents,² in the elderly it is relatively rare and confined to a few case reports.³⁻⁵

In the present report, we describe a patient with emergence of pedophilia in late life, the assessment, and response to treatment with sertraline.

Case report. Mr. A, a 70-year-old man, was hospitalized in 2005 with a history of engaging in sexual behavior with female children 6 to 7 years old. The history was obtained from Mr. A's adult son, as the patient initially denied any problem. During the last 13 years, Mr. A had been giving young girls money, later taking them to remote places and undressing them and fondling their genitals. On 1 or 2 occasions, he had apparently attempted intercourse (based on reports from the victims' families of vaginal bleeding). No legal complaint had been filed by the victims' families. However, Mr. A's family was concerned that he may molest these children and get arrested and thus locked him in the house often. He is married and heterosexually oriented and was living with his wife and children. The patient reported no recent change in the sexual relationship with the wife, which was corroborated by her. Mr. A's medical history was notable for a cataract surgery in the left eye 3 months before admission. He had no history of psychiatric or developmental problems and had exhibited no prior deviant sexual behavior. There was no history suggestive of cerebrovascular disease or dementia.

On examination, Mr. A was cooperative and had good eye-to-eye contact. His thought processes were logical and clear. He denied any hallucinations or delusions and appeared to be euthymic. He was alert and attentive and scored 29 of 30 on the modified Mini-Mental State Examination,⁶ missing an item in attention and concentration. Results of repetition, naming, memory, and constructional tasks were within normal limits. His ability to perform simple constructions was also within normal limits, and he had no difficulty with an alternating motor patterns test. Mr. A's neuropsychological assessment showed deficits in focused attention, design fluency, and visual working memory. His abstract ability was within normal limits. Physical examination, including detailed neurologic examination, found no abnormalities. Results of laboratory tests, including liver, thyroid, and renal function; hemogram; electrocardiogram; serum Venereal Disease Research Laboratory test; ELISA for human immunodeficiency virus; and serum testosterone levels (measured by chemiluminescent immunoassay), were all in the normal range. Structural magnetic resonance imaging of the brain showed findings within normal limits.

After a couple of weeks of inpatient stay, Mr. A corroborated his sexual attraction to young girls and recognized that this was a potential problem for him in the village. He fulfilled DSM-IV-TR criteria for pedophilia.¹ He was started on sertraline, 50 mg/day, which was increased to 100 mg/day after 3 weeks. He also became engaged in individual counseling, which initially involved establishing a therapeutic alliance and gaining the patient's confidence. With this regimen and increased supervision, Mr. A had a significant behavioral improvement with no reports of similar incidents during the next 1 year of follow-up and reported a decrease in desire on a visual analogue scale.

The index patient presented with late-onset sexual activity with prepubescent girls in the absence of schizophrenic, affective, obsessive, or dementia symptoms. In contrast to the typically reported cases of pedophilia, the index patient had an unusual presentation with emergence of pedophilia in late life.

The etiology of pedophilia is unknown. Paraphiliac behavior has been reported secondary to temporal lobe epilepsy, post-encephalitic neuropsychiatric syndromes, septal lesions, frontal lobe lesions, bilateral temporal lobe lesions, multiple sclerosis, and tumors in various sites.⁷ Recent reports have noted the concurrence of emergence of pedophilia in late life and brain disease. One report described 2 patients with pedophilia who had temporal lobe hypometabolism as revealed by positron emission tomography; 1 patient had frontotemporal dementia and the other had bilateral hippocampal sclerosis.⁴ No evidence of structural brain lesion, however, was evident in our patient.

Management of pedophilia at any stage poses a serious clinical challenge. Antiandrogens and hormonal agents such as estrogen, medroxyprogesterone acetate, cyproterone acetate, and gonadotropin analogues have been used; however, the effectiveness of treatment was reduced because of the various adverse reactions,⁷ and only a minority of subjects are likely to take an antiandrogen on their own. Several recent reports suggest successful treatment of paraphilias with selective serotonin reuptake inhibitors, e.g., sertraline, fluoxetine, and fluvoxamine.⁸⁻¹⁰ However, the efficacy of these drugs in the treatment of pedophilia emerging in late life is not known. The case reported here suggests the efficacy of sertraline in pedophilia. In the elderly, it is critical to evaluate for underlying structural and functional brain abnormalities.

Risperidone-Induced Neuroleptic Malignant Syndrome in Neurodegenerative Disease: A Case Report

Sir: Neuroleptic malignant syndrome (NMS) is uncommon with the use of atypical antipsychotics.¹ This report describes the case of a 34-year-old male with suspected neurodegenerative disease who developed this complication with the use of risperidone. He was successfully treated with dantrolene and bromocriptine and was discharged in stable condition after 7 days.

Case report. Mr. A is a 34-year-old white man known to have mild mental retardation (IQ estimate, 68). He was born through a first-degree consanguineous relationship. Prior to the illness reported here, he lived by himself and was able to perform activities of daily living without assistance or any medications. Eleven months ago, he started to develop slowing of movements. He was thoroughly investigated and diagnosed at that time with acute parkinsonism and was started on treatment with carbidopa/levodopa and benzotropine. Mr. A continued to show progressive cognitive deterioration and incontinence of bowel and bladder over the next 8 months and was moved to a nursing home 3 months ago. In addition, he began to have symptoms suggestive of major depression during the past 6 months and was started on paroxetine. Following improvement in his affective symptoms, paroxetine was gradually tapered and discontinued after 5 months. However, he began to develop psychotic features and was started on risperidone at a dose of 4 mg daily 3 weeks prior to his admission to our hospital. Within 48 hours of starting risperidone, he developed generalized muscle rigidity. However, risperidone was continued over the next 3 weeks until he developed hyperpyrexia and was admitted to a nearby hospital. He was treated there with antibiotics for 2 days, with a presumptive diagnosis of sepsis. Blood cultures, cerebrospinal fluid examination, and computed tomographic (CT) scan of the head showed no abnormal findings. Subsequently, he was transferred to our hospital, as he showed no improvement.

Upon admission to our hospital, Mr. A was hyperthermic (104.4°F), hypertensive (blood pressure, 138/79 mm Hg), tachycardic (heart rate, 146 beats/min), tachypneic (respiratory rate, 28 breaths/min), and unresponsive. He had a startled facial expression and was drooling. Mr. A maintained a decorticate posture and had lead-pipe rigidity in all limbs. Eye movements were conjugate, and pupils were equal and reactive to light. Deep tendon reflexes were brisk and symmetric. Primitive reflexes and jaw jerk were also present. Toes were up-going bilaterally. The remainder of his physical examination was unremarkable.

Blood tests showed leukocytosis, but electrolytes were within the normal range. He was given a presumptive diagnosis of NMS in accordance with DSM-IV criteria. Risperidone and antibiotics were discontinued, and prompt treatment with ice packs and intravenous dantrolene and bromocriptine was instituted. Hyperpyrexia resolved completely within a few hours. Repeated blood and urine cultures were sterile. The rigidity in his lower limbs improved over a few days; he was treated with baclofen, carbidopa/levodopa, and benzotropine for persistent rigidity in the upper limbs. Mr. A subsequently did well, was observed for a period of 7 days, and was discharged in stable condition.

NMS is a potentially life-threatening complication of neuroleptic therapy, with a mortality rate of 11.6%.² The mecha-

nism of hyperthermia in NMS is believed to be dopamine D₂ receptor antagonism that results in blockage of heat-loss pathways in the anterior hypothalamus and/or increased heat production secondary to extrapyramidal rigidity.³

Risperidone, a benzisoxazole-derivative antipsychotic with high serotonin (5-HT)₂ receptor blockade and dose-related D₂ receptor blockade, was not expected to cause NMS at low dosages. However, in recent years, numerous cases of NMS have been reported with atypical antipsychotic medications including clozapine, olanzapine, quetiapine, and risperidone.⁴ The results of 1 study suggested that a disturbance of serotonin metabolism may be implicated.⁵ Mortality has been reported to be lower in NMS associated with atypical antipsychotics.⁴

The patient demonstrated high fever, generalized rigidity, and altered mental state. There is considerable potential for diagnostic confusion between NMS and neurotoxicity from atypical antipsychotics because of overlap of features such as benign hyperthermia and autonomic instability.¹ An infectious process should always be ruled out before a diagnosis of NMS is considered. Differentiation from serotonin syndrome is critical for successful management in cases with concomitant use of selective serotonin reuptake inhibitors (SSRIs). However, the absence of incidental use of SSRIs and the lack of myoclonus and gastrointestinal dysfunction, which are typical symptoms of serotonin syndrome, suggest that serotonin syndrome was not the diagnosis in our patient. Our patient's symptoms fully met the diagnostic criteria for NMS put forth by DSM-IV,⁶ Levenson,⁷ Pope et al.,⁸ and Caroff and Mann.⁹

Most cases of risperidone-induced NMS have occurred within the first month of risperidone use, as in the case of our patient. One case series has even described the presence of a "striking, frightened facial expression" in all cases of NMS,¹⁰ as was present in our patient.

Organic brain disease and mental retardation have been identified as risk factors for NMS.^{2,10} The history of first-degree consanguinity and preexisting psychiatric symptoms with cognitive decline and parkinsonism exhibited by our patient may indicate the presence of a rare inherited neurodegenerative disorder such as adult neuronal ceroid lipofuscinosis (ANCL) (Kufs' disease). Studies have shown that patients with ANCL are more susceptible to NMS with the use of typical neuroleptics due to disturbances in the calcium metabolism of muscle cells.¹¹ The loss of dopaminergic neurons in this condition may make these patients more vulnerable. Increased susceptibility to NMS has also been reported in Parkinson's disease¹² and in dementia with Lewy bodies.¹³ Affective illness is another risk factor for NMS.¹⁰

The initial step in the treatment of NMS is the discontinuation of the causative agent. The mainstays of treatment include fluid and electrolyte replacement, reduction of temperature, and support of cardiac, respiratory, and renal functions. Pharmacotherapy with bromocriptine, dantrolene, and amantadine and electroconvulsive therapy have been described to be effective.¹⁴ Our patient received dantrolene, bromocriptine, benzotropine, carbidopa/levodopa, baclofen, and intravenous fluid replacement.

Clinicians need to be aware that NMS can occur with risperidone, despite the markedly lower incidence of extrapyramidal symptoms. In patients with neurodegenerative disorders, caution should be exercised in prescribing even atypical agents, and a high index of suspicion for NMS should be maintained. Further study is needed to reveal the mechanism of risperidone-induced NMS.

The authors report no financial affiliations or other relationships that can be considered a conflict of interest relevant to the subject of this letter.

Vitamin B₁₂ Deficiency Manifested as Mania: A Case Report

Sir: Multiple psychiatric symptoms may precede pernicious anemia. Only 1 case of full manic syndrome secondary to B₁₂ deficiency has been reported.¹

Case report. Ms. A was a 35-year-old woman with no personal or family history of psychiatric disorders, who was admitted to the hospital in February of 2005 with a 3-week history of episodes of manic symptoms of several hours' duration, including grandiosity, hyperactivity, sexual indiscretion, hyperphagia, irritable mood, reckless behavior, flight of ideas, and overbearing manner. These episodes had a sudden onset and conclusion, and the patient was able to remember them. No hallucinations were reported at any time.

At admission, she was oriented in all spheres, but was easily distractible. Full manic syndrome (DSM-IV criteria) was

present and there was no coexisting delirium. All these psychiatric symptoms disappeared after 1 hour, without any medical intervention.

An examination revealed the presence of a left Babinski's reflex and ataxia, as well as a bilateral loss of proprioception, vibration, and sensation of light touch and pain in the lower extremities. Strength and reflex in the lower extremities were diminished.

The results of general blood chemistries, a thyroid function test, and a comprehensive drug screen were within normal limits. Although the results of electroencephalogram (EEG) and brain magnetic resonance imaging were normal, the duration, as well as the sudden onset and conclusion of episodes, suggested an epileptic cause for this patient's mania.² Ms. A was treated with valproic acid for 3 weeks with no improvement.

Serum vitamin B₁₂ level was measured and was found to be markedly diminished—less than 60 pg/mL. Vitamin B₁₂ (1000 µg/day) was administered intravenously for 1 week. After the third day of B₁₂ replacement therapy, our patient did not experience new manic episodes. Therapy was continued with 1000 µg intramuscular injections weekly for 1 month and then with monthly intramuscular injections as maintenance treatment. Within 1 month, neurologic symptoms had improved. One year after B₁₂ vitamin replacement started, her mental status was still normal.

Although many psychiatric symptoms have been considered to be related to B₁₂ deficiency,^{3,4} this is the first report of short duration episodes of manic symptoms secondary to B₁₂ deficiency. The absence of previous psychiatric or medical disorders, coupled with her continued clinical remission while she was receiving B₁₂ alone, argues that B₁₂ deficiency was the most likely cause of her psychiatric disorder.

Our case could also raise the hypothesis of different neurobiological mechanisms underlying mood disorders and the importance of B₁₂ and folate in their genesis.⁵

Case Report: Bupropion-Induced Claustrophobia

Sir: Although emergent anxiety can occur with bupropion therapy (5%–6% per the package insert¹), to date there are no reports of claustrophobia associated with the drug. We present a case of new-onset claustrophobia related to bupropion therapy.

Case report. Mr. A, a 59-year-old man with no prior psychiatric history, was prescribed bupropion in May of 2005 for a major depressive episode (DSM-IV criteria). Target symptoms included decreased energy, feelings of worthlessness, decreased appetite, and restlessness. Past treatment consisted of sertraline (taken from December 2004 to January 2005), discontinued due to sexual side effects, and citalopram (prescribed once in March 2005), discontinued for lack of efficacy.

The patient was administered bupropion SR, titrated to 150 mg twice daily. Soon after, he self-decreased his dose to 150 mg daily because of irritability and “claustrophobia,” described as an intense feeling that the walls were closing in. He also reported increased heart rate, diaphoresis, and difficulty breathing while in rooms with closed doors, in elevators, in the shower, and in the back seat of compact cars. These symptoms were not present in situations that did not involve enclosed spaces. In clinic, he insisted the office door be left open. Bupropion was subsequently discontinued (June 29, 2005) and venlafaxine was initiated on the same day. After 1 month, his claustrophobic symptoms resolved. Nine months after bupropion therapy was terminated, anxiety symptoms have not recurred.

Claustrophobia is an anxiety disorder that involves the fear of confined or enclosed spaces.² Although one of the most prevalent specific phobias in the general population, only 20% of those affected will seek medical attention.³ Thus, the disorder often goes undiagnosed.

Although the exact pathophysiology of claustrophobia is unknown, there is compelling evidence that supports the role of the noradrenergic system in anxiety disorders. The activation of brain noradrenergic neurotransmission in the presence of acute stress results in neuroendocrine, autonomic, behavioral, and cognitive responses.^{4,5} Unlike other agents, bupropion exerts its therapeutic effects by inhibiting norepinephrine and dopamine reuptake.

Because of its actions on the noradrenergic system, it is reasonable that bupropion may worsen anxiety. In a study by Ashton and Rosen,⁶ 15% of patients treated with bupropion for sexual side effects associated with selective serotonin reuptake inhibitors discontinued therapy due to anxiety or tremor. Additionally, Young⁷ reported a case of panic occurring following the addition of bupropion to fluoxetine.

To our knowledge this is the first report of bupropion-induced claustrophobia. We recommend caution with the use of bupropion in patients with primary anxiety disorders.

Is There an Alternative to Seclusion or Mechanical Restraint?

Sir: The treatment of agitated patients has been reviewed in the literature.¹ We would like to comment on the use of restraints and seclusion for such patients. We agree that mechanical restraints or seclusion should be the last measure used in the majority of cases, but think that application of such methods is sometimes necessary. A decline in the use of seclusion or mechanical restraint due to administrative regulation might be dangerous and the reason for increased violence on psychiatric wards.² Furthermore, some patients have been known to request placement in seclusion³ or to be mechanically restrained. Although significant literature exists, there is a lack of knowledge about patients' attitudes toward these methods independent of personal experiences.

Method. Attitudes of currently hospitalized patients with schizophrenia toward use of mechanical restraints (seclusion is a rare practice in Croatia) were examined. We constructed a questionnaire consisting of questions mostly related to patients' emotional reactions toward use of mechanical restraints and to the phenomenon of aggression on psychiatric wards. The participants gave consent to participate in the study after the purpose was explained. Data were collected in August 2006. Although 120 patients agreed to participate in the assessment, 13 patients (11%) refused further participation during assessment and 36 (30%) failed to provide analyzable data because of poor psychiatric states. Analyzable data were collected from 71 patients (59%) (male = 54, female = 17; mean [SD] age = 41.47 [12.62] years, range, 19–70 years; mean [SD] duration of disorder = 12.70 [9.03] years; 11 patients had been treated on “acute wards,” 23 on “chronic wards,” and 37 at the Department of Forensic Psychiatry).

Results. Of the final sample, 61 patients (86%) had the opinion that mechanical restraint was sometimes necessary, and 42 (59%) had the attitude that mechanical restraint of another aggressive patient reduced their feeling of insecurity. Thirty-two

patients (45%) had been mechanically restrained 1 or more times. Of those who had been mechanically restrained, 17 (53%) had the attitude that, in their case, restraint was, at least once, necessary; 11 (34%) requested restraints 1 or more times; and 12 (38%) had experienced feelings of being safer during restraint.

We agree that, in terms of clinical guidelines, mechanical restraints or seclusion should be used for the least amount of time possible. Yet, use of restraints influences the "atmosphere on a ward." In accordance with our results, decreasing feelings of insecurity or danger, which are present in a significant number of patients on the psychiatric ward, is part of that "atmosphere."

Furthermore, we think that, in some cases, fortunately rare, feelings of insecurity among patients in the ward might become the reason for prolonged use of seclusion or mechanical restraint. For example, hostile attack of a patient by another patient might lead to increased feelings of insecurity among other patients on the ward. Feelings of insecurity among the other patients might be so intense that, independent of the psychiatric state of the patient who made the attack, seclusion or restraints should be used for longer periods of time. In similar cases, these methods might paradoxically protect the restrained patient from his or her environment. We do believe that such situations are more frequent on forensic wards, but are possible on all kinds of wards.

Massive Epistaxis and Subconjunctival Hemorrhage Due to Combination of Paroxetine and Limaprost Alfadex: A Case Report

Sir: A patient presented to us having experienced a few days of massive epistaxis and hyposphagma (severe hemorrhage into the conjunctiva) while taking paroxetine. Pharmaceutical use was also notable for the peripheral vasodilator limaprost alfadex. To our knowledge, no such case has been reported in the literature. We believe the combination of paroxetine and limaprost alfadex led to the bleed.

Case report. Ms. A, a 66-year-old woman with blood counts and blood coagulation tests within normal limits, presented in June 2005 to the orthopedic surgery department with com-

plaints of coldness of limbs, continuing lower-extremity pain, insomnia, and loss of appetite. She underwent a nerve-root block for lumbar spinal canal stenosis and started limaprost alfadex 15 μ g/day. Limaprost alfadex, an oral prostaglandin E₁ derivative, is frequently used in Japan for the treatment of peripheral circulatory disturbances. Because the symptoms overall did not improve, she was referred to the psychiatry service (July 2005). She had lost 10 kg in 2 months and complained strongly of anxiety and frustration due to inability to do household and to memory loss. She was admitted in September 2005.

The patient was diagnosed with DSM-IV major depressive disorder with psychotic features based on hypochondriacal and persecutory delusions and aggression. When she refused food and medication due to delusions of being poisoned, electroconvulsive therapy (ECT) was introduced (October–November 2005, total of 11 treatments). ECT was effective, and she began to take medication again after the sixth ECT treatment. She was restarted on limaprost alfadex treatment (15 μ g/day). When ECT was completed in early November, paroxetine 20 mg/day was started, increasing to 40 mg/day after 2 days and to 50 mg/day after 4 days. The patient's mood remained normal.

On the 29th and 30th days after starting paroxetine, she experienced massive epistaxis (more than 500 mL per episode). On the 30th day of treatment, paroxetine was decreased to 40 mg/day, but similar epistaxis recurred the next day. An otolaryngologist determined that hemorrhage was from the right Kiesselbach plexus; however, no other abnormality was observed. Complete blood count and blood coagulation findings were within normal limits. On the 36th day of paroxetine treatment, limaprost alfadex was reduced from 15 μ g/day to 10 μ g/day. No further epistaxis episodes occurred. Upper (day 45 of paroxetine treatment) and lower (day 50 of paroxetine treatment) gastrointestinal endoscopy were performed, and no hemorrhage was observed. Because of intermittent complaints of lower extremity coldness and pain, the dosage of limaprost alfadex was returned to 15 μ g/day. Since January 2006, prescriptions for paroxetine 40 mg/day and limaprost alfadex 15 μ g/day have continued, and the patient has been followed at the outpatient clinic. There has been no recurrent epistaxis as of September 2006. However, right eye hyposphagma was recently observed at a psychiatry clinic appointment. If this continues, we will consider decreasing paroxetine to 30 mg/day.

Mild epistaxis during selective serotonin reuptake inhibitor (SSRI) treatment is a well-known rare adverse effect, but our patient's epistaxis was severe. Hyposphagma with paroxetine might be very rare.¹ Since only a few case reports² have suggested SSRI use alone can trigger even mild bleeding, including ecchymoses, purpura, and epistaxis, we cannot make a strong conclusion. After carefully examining the drugs in concurrent use for our patient, it is quite possible that limaprost alfadex, in combination with paroxetine, contributed to severe epistaxis and hyposphagma.

When patients present with severe symptoms, including psychotic features, many clinicians use relatively high doses of antidepressants for continuation and maintenance treatment.³ Because vasodilating prostaglandins such as limaprost alfadex are used frequently in fields such as orthopedic surgery, it is important that clinicians know there may be a tendency for hemorrhage when an SSRI is also used; physicians should consider decreasing the SSRI maintenance dose in such instances.

The Tolerability of Oral-Loaded Valproate After Remission of Acute Mania in Japanese Patients With Bipolar Disorder

Sir: It has been reported by McElroy et al.¹ that the onset of the antimanic effects of valproate can be accelerated by administering valproate at a loading dose of 20 mg/kg/day and that doing so produces a rapid response with minimal side effects. Since then, several studies^{2,3} have shown that oral-loaded divalproex is an effective and well-tolerated treatment in patients with acute mania. However, these previous studies were limited to analysis of acute treatment effects. The tolerability of continuing the initial dose of valproate after the remission of mania has yet to be established. We conducted a naturalistic observational study to assess the safety of continuous treatment with valproate at high doses in bipolar patients.

Method. The study included 9 patients, aged 24 to 79 years (7 female, 2 male), who presented for the treatment of acute mania to the Hiroshima University hospital from July 2002 through December 2004. All patients were diagnosed with acute mania associated with bipolar I disorder according to DSM-IV criteria. Two were diagnosed with rapid-cycling bipolar disorder. The nature and purpose of the study were explained, and informed consent was obtained from all patients. The study was conducted according to a protocol approved by the Ethics Committee of the Hiroshima University School of Medicine. Patients were required to have manic symptoms of sufficient severity to have Young Mania Rating Scale (YMRS)⁴ scores of 23 or more. Remission was defined as achieving YMRS scores under 8. The mean \pm SD YMRS score at baseline was 34.6 ± 5.1 . Other psychotropics (antipsychotics and benzodiazepines) were allowed for the treatment of agitation or insomnia if necessary. Valproate was administered at 20 mg/kg/day or 30 mg/kg/day for at least 4 weeks. The mean YMRS scores were analyzed by Scheffe's multiple comparison test following repeated-measures analysis of variance.

Results. All 9 patients received valproate treatment at the initial dose for at least 4 weeks. The mean valproate loading dose was 1360 mg/day. Serum levels of valproate were greater

than 50 μ g/mL by day 4 in all patients. All patients showed significant improvement, and the mean \pm SD YMRS score was 21.4 ± 4.5 at the end of week 1 ($p < .0001$). At the fourth week, all achieved remission, and their mean \pm SD YMRS score was 3.0 ± 2.4 . The mean serum level of valproate after the patients' mania had stabilized was about 95 μ g/mL. No adverse events were reported during the first 4 weeks of treatment. The results confirmed that oral loading of valproate for up to 4 weeks is a safe and effective treatment for Japanese patients with acute mania.

However, by week 12, 8 of 9 patients had reported adverse effects, including sedation (8 patients), nausea (1 patient), and weight gain (1 patient), and 8 patients had their dose reduced as a consequence. Three patients who were followed beyond the 12-week follow-up period discontinued valproate because of adverse effects.

Previous studies¹⁻³ showed that oral loading with valproate for 10 days or less is well tolerated in the majority of patients with acute mania. Our study demonstrates that continuing high-dose valproate may cause adverse effects in Japanese patients with bipolar disorder. Thus, the doses of valproate may need to be decreased after remission. Further controlled examinations are needed to ascertain whether it is necessary to decrease the dose after remission and whether a lower dose of valproate is effective for maintenance treatment.

This study was supported by the Research Grants for Nervous and Mental Disorders from the Ministry of Health, Labor and Welfare, Japan, in 2005.

The authors report no additional financial relationship or affiliation relevant to the subject of this letter.
